

Parameter-free Regression-based Autonomous Control of Off-the-shelf Quadrotor UAVs

Rahul Peddi and Nicola Bezzo

Abstract—Autonomous flight in unmanned aerial vehicles (UAVs) generally require platform-specific knowledge of the dynamical parameters and control architecture. Recently, UAVs have become more accessible with off-the-shelf options that are well-tuned and stable for user teleoperation. In this paper, we develop a method to enable autonomous flight on vehicles that are designed for teleoperation with minimal knowledge of the system parameters and the control architecture. The proposed method leverages human teleoperated trajectories to train a thin-plate spline (TPS) regression model, which is then used with image processing on the pre-trained commands to generate new autonomous input commands for new trajectories. A control strategy is also proposed to adjust autonomous input commands in real-time, in order to close the loop for assured autonomy. Finally, we validate the proposed approach with trajectory-following experiments on a quadrotor UAV.

I. INTRODUCTION

Unmanned Aerial Vehicles (UAVs) have become widespread for both civilian and military applications in recent years. There are several applications for which UAVs are uniquely suited over other robotic systems, such as surveillance, delivery services, and search and rescue. All of these applications require the UAV to autonomously follow trajectories to different goal or task locations. For example, a package delivery UAV may have to autonomously reach multiple locations at certain times to deliver and receive new packages.

The development of dedicated platforms for such autonomous tasks can be expensive and not necessary since hundreds of off-the-shelf UAVs are available nowadays and for low cost. These platforms are usually well designed, very stable, and ready to fly out of the box but are typically restricted to teleoperation usage.

Generating autonomous flight behavior - subject of this paper - however, can be difficult since every UAV has a different dynamical model, which is typically not available, and reverse engineering is often not possible. Model-based approaches that include system identification, model extraction, and control design are well known procedures to deal with this issue however they are time demanding and often not precise requiring a lot of tuning and testing [1]. Even when these approaches are successful, among similar vehicles there can be model mismatch due to manufacturing error, different usage, physical changes, or aging which can change parameters thus needing more tuning or sophisticated

adaptive control architectures to guarantee safe and reliable control.

On the other hand, data-driven machine learning techniques like neural networks, reinforcement learning, and regression techniques have recently emerged and have demonstrated to be effective to learn from training data. The main drawbacks of such procedures is that there is still not a clear reasoning about how these techniques work and typically large and dense training sets are required to obtain precise results.

In this work we propose a novel approach that leverages both model-based and data-driven theories to generate autonomous flight behavior for an aerial vehicle from few user teleoperation demonstrations. We focus on off-the-shelf quadrotor UAVs which have a well studied dynamical and control architecture as will be described later in the paper and are by far the most common UAVs because of the growing hobby and DIY community. Even if the application focus of this paper is on quadrotors, our framework can scale and apply to any other aerial vehicle. Fig. ?? shows some examples of such quadrotors focus of this paper, all characterized by having the same shape but different motors, propellers, boom size, and electronics and hence different dynamic and control models.

Different from other supervised learning approaches, in this work we leverage the knowledge about the generalized architecture for the UAV dynamics and their controller and use regression-based techniques to extract a model for closed loop trajectory tracking. The main contribution of this work is a generalized framework that combines both model-based and data-driven theories to generate autonomous control for aerial vehicles. ♠¹ ♠²

II. RELATED WORK

♠⁴

In recent years, we have seen many developments in the study of unmanned aerial vehicles (UAVs). A very common and widely researched task for UAVs is controlling a vehicle such that a certain trajectory can be followed. The authors in [2]–[4] provide well optimized approaches for UAV trajectory generation and tracking by utilizing near perfect knowledge of the controller and dynamical model

¹NB: need to reinforce this statement

²NB: need to add a figure here that summarizes the approach

³NB: we need to stress that these quadrotors already come with well designed controllers and at the bare minimum we can teleop

⁴NB: skipping related work for now

parameters. Access to these parameters, as they are in our case, are often limited. In [5], the authors leverage exact knowledge of the model dynamics and controller architecture to identify necessary parameters for trajectory tracking, and perform parameter estimation using particle swarm optimization, which the authors state can be a long and iterative process, which is the case for many other model-based parameter and system identification works [1], [6].

Some of the more recent advancements in this area feature machine learning and data-driven approaches, such as deep learning (DL), imitation learning (IL), and reinforcement learning (RL). In [7], the authors use DL to learn driving models for ground vehicles by using large-scale video datasets, and in [8], the authors use RL over 1,000 training samples for accurate quadrotor trajectory tracking. These methods are model and parameter free, but use extremely large datasets to resolve that issue. In [9], the authors explore the idea of observational imitation learning (OIL), where they learn from a relatively small number of demonstrations, but also assume knowledge of the controller architecture and perform parameter estimation, which can be a daunting task without knowledge of the controller architecture. The authors in [10] use apprenticeship learning, which is similar to IL, to train a UAV to perform trajectories with a very simplified model, but there is still a necessity to learn some dynamical parameters, while assuming knowledge of several others. Despite having to learn certain parameters, these authors show the ability to learn trajectory tracking using only important information from only 20 minutes of flight time. The understated desire for smaller training sets is prevalent in many of the works in this area. Some works, such as [11] use a stochastic method known as a Gaussian Process (GP) to accurately tune a simplified UAV controller. Use of stochastic or regression based methods, such as GPs have shown the ability to execute imitation learning with limited training sets and information [12], [13].

Our work is largely based on combining the aforementioned apprenticeship learning theory with a regression method - we show how we can obtain and analyze important information from a relatively small number of demonstrations. Contrary to the model based approaches, we assume no knowledge of specific dynamical parameters, and only a basic idea of the structure of the dynamical model and controller architecture. This makes parameter estimation a rather unfeasible and inefficient task. Instead, we use information obtained from our human-piloted training demonstrations to directly generate control inputs to track any trajectory, by way of training and analyzing a regression model and implementing online adaptive loop-closure.

III. PROBLEM FORMULATION

In this work, we are interested in developing autonomous navigation for a UAV by leveraging knowledge about its system dynamics and controller and by leveraging a set of human-piloted demonstrations. Formally, the problem we investigate in this work can be stated as:

Problem 1: Parameter-free Autonomous Control of UAVs: Consider a pre-configured off-the shelf ready to fly UAV, with known model architecture $\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u}, \mathbf{p})$ and control architecture $\mathbf{u} = g(\mathbf{y})$ and unknown internal parameters \mathbf{p} . Design a policy to generate the sequence of inputs \mathbf{u} to track a user defined reference trajectory $\mathbf{x}_r(t)$, $t \in [0, T]$ over a finite user defined horizon T . Specifically the policy should guarantee that the UAV position $\mathbf{p}(t)$ is always within a certain threshold δ_d from the generated trajectory position $\mathbf{p}_r(t)$

$$\|\mathbf{p}(t) - \mathbf{p}_r(t)\| \leq \delta_d, \forall t \in [0, T] \quad (1)$$

where $\|\cdot\|$ is the Euclidean norm.

IV. SYSTEM MODELS

As hinted in the introduction, we use knowledge about the UAV dynamics and control architecture to extract useful information about the system to guide a regression approach for the generation of autonomous control commands for the UAV. We focus on off-the-shelf tuned and stable quadrotors that typically are ready for teleoperation but not for autonomous flight. The control architecture of the off-the-shelf quadrotor is shown in Fig. 1.

Fig. 1. Off-the-Shelf UAV Teleoperation Control Architecture

The presented structure is a gray box model, where the only information known are the teleoperation inputs, indicated by \mathbf{J}_x and \mathbf{J}_y ⁵, the output, which is the position of the vehicle, $\mathbf{p}(t)$, over time, and the basic model architecture. The low level controller usually consists of multiple PID loops [14], which are already developed and tuned with certain specific control gains, which can be very difficult to identify by analyzing the output of the system. The quadrotor body dynamics can be modeled using a 12th order state vector as follows:

$$\mathbf{q} = [\mathbf{p}^T \quad \phi \quad \theta \quad \psi \quad v_x \quad v_y \quad v_z \quad \omega_x \quad \omega_y \quad \omega_z]^T$$

⁶ where $\mathbf{p}_q = [x \ y \ z]^T$ is the world frame position, v_x , v_y and v_z are the world frame velocities, ϕ , θ and ψ are the roll, pitch and yaw Euler angles and ω_x , ω_y and ω_z are the body frame angular velocities.

⁵NB: instead of \mathbf{J} please use \mathbf{bm} everywhere

⁶NB: use \mathbf{p}_q

The dynamics of the vehicle are then described as follows:

$$\begin{aligned} \dot{\mathbf{p}}^T &= [v_x \ v_y \ v_z] \\ \begin{bmatrix} \dot{v}_x \\ \dot{v}_y \\ \dot{v}_z \end{bmatrix} &= \begin{bmatrix} 0 \\ 0 \\ -g \end{bmatrix} + \frac{1}{m} \begin{bmatrix} \cos \phi \cos \psi \sin \theta + \sin \phi \sin \psi \\ \cos \phi \sin \theta \sin \psi - \cos \psi \sin \phi \\ \cos \theta \cos \phi \end{bmatrix} u_1 \\ \begin{bmatrix} \dot{\phi} \\ \dot{\theta} \\ \dot{\psi} \end{bmatrix} &= \begin{bmatrix} 1 & \sin \phi \tan \theta & \cos \phi \tan \theta \\ 0 & \cos \phi & -\sin \phi \\ 0 & \sin \phi \sec \theta & \cos \phi \sec \theta \end{bmatrix} \begin{bmatrix} \omega_x \\ \omega_y \\ \omega_z \end{bmatrix} \\ \begin{bmatrix} \dot{\omega}_x \\ \dot{\omega}_y \\ \dot{\omega}_z \end{bmatrix} &= \begin{bmatrix} \frac{I_{yy} - I_{zz}}{I_{xx}} \omega_y \omega_z \\ \frac{I_{zz} - I_{xx}}{I_{yy}} \omega_x \omega_z \\ \frac{I_{xx} - I_{yy}}{I_{zz}} \omega_x \omega_y \end{bmatrix} + \begin{bmatrix} \frac{1}{I_{xx}} & 0 & 0 \\ 0 & \frac{1}{I_{yy}} & 0 \\ 0 & 0 & \frac{1}{I_{zz}} \end{bmatrix} \begin{bmatrix} u_2 \\ u_3 \\ u_4 \end{bmatrix} \end{aligned}$$

[15]

This dynamical model consists of many platform-specific parameters that are also difficult to identify, much like the controller gains discussed above. Moreover, these parameters often vary a lot between UAVs, and that further complicates the identification problem. The model and architecture above assume that the quadrotor is moving at a constant z level with a zero yaw constraint, and therefore, we are primarily concerned with two of the inputs, u_2 and u_3 . The equations for the control inputs are as follows:

$$\begin{aligned} u_2 &= k_{p,\phi}(\phi_c - \phi) + k_{d,\phi}(\dot{\phi}_c - \dot{\phi}) \\ \phi_c &= -\frac{1}{g}(\ddot{x}_{des} + k_{d,x}(\dot{x}_{des} - \dot{x}) + k_{p,x}(x_{des} - x)) \\ u_3 &= k_{p,\theta}(\theta_c - \theta) + k_{d,\theta}(\dot{\theta}_c - \dot{\theta}) \\ \theta_c &= -\frac{1}{g}(\ddot{y}_{des} + k_{d,y}(\dot{y}_{des} - \dot{y}) + k_{p,y}(y_{des} - y)) \end{aligned} \quad (2)$$

where ϕ_c and θ_c are the desired roll and pitch angles, respectively.

In this work, we are interested in generating control inputs for autonomous flight when the only information available for training comes from human-piloted demonstrations. Given these user demonstrations, we assume that the inputs and outputs for the UAV are visible, i.e., we can obtain position and the velocity of the system during training as well as the input commands sent to the vehicles from the user teleoperation. Through observation of a single demonstrated trial, we are able to identify important commands sent to the system. An example of this \spadesuit^7 is shown below \spadesuit^8 :

\spadesuit^9 In Fig. 2, we show a sample of a single flight demonstration on a Parrot BeBop 2 quadrotor which is a hobby-grade quadrotor. The pilot flies the UAV forward over a distance of approximately 3 meters, with initial and final velocities of 0. The teleoperation input command string, in this case, corresponds to pitch, where a command of 0 would imply no pitch adjustment, and 1 corresponds to the UAV's maximum allowable pitch. The minimum allowable pitch

Fig. 2. A sample of a single demonstrated flight

command is -1 , which would send the UAV in the negative y -direction. \spadesuit^{10}

From (2), we observe that the inputs u_2 and u_3 for roll and pitch rely on the change in the desired Euler roll ϕ_c and pitch θ_c angles, and these desired roll and pitch angles are a function of the desired positions and velocities which are provided by the user in our work. Hence, each stroke in the joystick transforms into motion of the vehicle which in turns affect its changes in the global x and y position. Our first goal here is to understand this mapping between user inputs and distance traveled by the quadrotor to build an autonomous behavior. Instead of using the entire string of commands, which could be large, not uniform, and computationally expensive, in this work we use the integral of the commands, in other words the area underneath the time series of commands which is a compact measure for training a model. The shaded area in Fig. 2 represents this integral.

Because the integral by itself may not be enough to characterize a unique behavior of the UAV because the same integral can be achieved with commands strings for different traveling distance and velocities, here we collect also the average command. By using the combination of integral and average input commands we can improve precision during the process of generating autonomous commands during missions, which consists in selecting a certain distance and time during run-time.

V. METHODOLOGY

The proposed approach is outlined in Fig.3. The approach begins with multiple demonstrations that are used to build a regression model that enables identification of the desired integral of the input commands, g_u , and desired average teleoperation input command, \bar{j}_u , given a user-set target distance, d_u , and time, t_u . With the integral and average velocity, a new command string consisting of commands for both lateral and longitudinal directions is created using the models within

⁷NB: this what? We cannot use this without any object on papers

⁸NB: avoid below above...they are vague...specify the figure number

⁹NB: we should show this picture in parallel with the speed and position of the vehicle to connect with the integral

¹⁰NB: just so we remember to mention somewhere: this command from the joystick could be anything...velocity acceleration, torque, voltage...and the approach will be able to relate that command with the change of velocity and position in the system

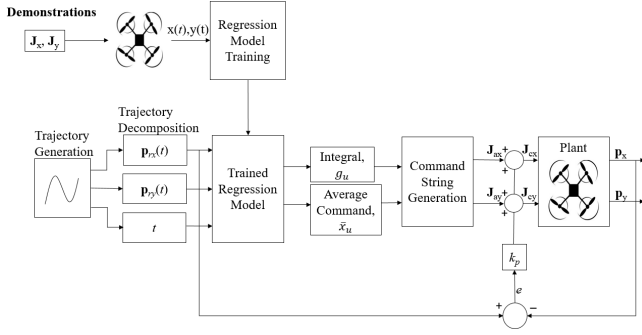

Fig. 3. Block Diagram of Proposed Approach

training set. At this stage, we generate the inputs, $\mathbf{J}_x(t)$ and $\mathbf{J}_y(t)$, needed by the system to follow the given trajectory. Because these actions are created in open-loop, accurate trajectory tracking cannot be guaranteed. Tracking error is reduced by closing the loop via a robust control approach to correct and adjust future inputs $\mathbf{J}_x(t+1)$ and $\mathbf{J}_y(t+1)$ to obtain closed loop input commands $\mathbf{J}_{cx}(t+1)$ and $\mathbf{J}_{cy}(t+1)$. First, we will discuss the trajectory decomposition, as our problem ultimately is to accurately track any trajectory.

A. Trajectory Generation and Decomposition

In this section, we discuss how a smooth trajectory is generated between waypoints, and how this trajectory is decomposed into x and y components. From the system dynamics, we know that input commands are responsible for specific motions of the system. Roll enables lateral motion while pitch enables longitudinal motion. Therefore, any planar motion assuming constant z and yaw can be represented as a combination of roll and pitch commands, or commands that move the vehicle along the global x and y coordinates. Because the using just roll and pitch commands is possible, we desire to decompose the trajectory into x and y components, as any smooth trajectory can be represented as a combination of these components.

In order to generate a trajectory, we first select waypoints through which the UAV should travel. In order to determine the optimal path in our case, we generate a minimum snap trajectory. Minimum snap trajectories are associated with low control effort as they are based on the fourth derivative of position and ensure smoothness [2]. The general equation for a minimum snap trajectory is as follows:

$$\mathbf{p}^*(t) = \arg \min_{\mathbf{p}(t)} \int_0^T \mathcal{L}(\ddot{\mathbf{p}}, \ddot{\mathbf{p}}, \dot{\mathbf{p}}, \dot{\mathbf{p}}, \mathbf{p}, t) dt \quad (3)$$

Solving (3), we obtain the form:

$$\mathbf{p}^*(t) = c_7 t^7 + c_6 t^6 + c_5 t^5 + c_4 t^4 + c_3 t^3 + c_2 t^2 + c_1 t + c_0 \quad (4)$$

where c_0, \dots, c_7 are constants associated with specific waypoints in the trajectory. ¹¹ Having obtained the smooth trajectory, we then discretize the trajectory into n parts, each

¹¹NB: we need to think if these equations are really necessary here. for now leave them but keep the comment

of which will have a time-step of $\delta t = \frac{T}{n}$, where T is the total amount of time allotted for the full trajectory. The discretization is done using linear interpolation within the trajectory over the interval $[\mathbf{p}^*(t_s), \mathbf{p}^*(t_{s+1})]$, where t_s is the time at the start of a segment and t_{s+1} is the end of the segment, defined as: $t_{s+1} = t_s + \delta t$. Some examples of decomposed trajectories are shown in Fig.4. All of the trajectories shown in Fig.4 start at the world frame origin $(0, 0)$.

Fig. 4. Discretized Trajectories

From the discretized trajectory, we can obtain the x and y components of each leg of the trajectory. Each component is calculated as follows:

$$\begin{aligned} c_x(t_s, t_{s+1}) &= \mathbf{p}_x^*(t_{s+1}) - \mathbf{p}_x^*(t_s) \\ c_y(t_s, t_{s+1}) &= \mathbf{p}_y^*(t_{s+1}) - \mathbf{p}_y^*(t_s) \end{aligned} \quad (5)$$

where $c_x(t_s, t_{s+1})$ and $c_y(t_s, t_{s+1})$ are the distances between each segment in x and y directions. These values are taken for each of the n trajectory segments with the same time-step, δt , and are appended to one another to create the desired output for which we will generate input commands. In Fig. 5, we show an example of a generated trajectory with its discretization and the x and y components that are stitched together.

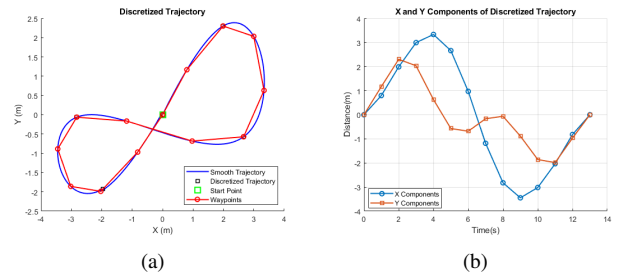

Fig. 5. Example of a Generated Trajectory with its x, y Decomposition

In Fig. 5(b), we show the components at each interval. These components, when executed simultaneously, correspond to the trajectory pictured in Fig. 5(a). Having obtained the trajectory x and y components, we will now discuss the training and command generation procedures that we use to build a policy that enables autonomous tracking of the trajectory.

B. Regression Based Training and Evaluation

In order to build the appropriate policy for autonomous command generation, we perform offline training on data collected over m human-piloted trials. As our goal is to

track a trajectory, we are interested in training on the distance traveled in the demonstrated trajectory, the time in which the pilot was able to traverse the trajectory, and the sequence of user teleoperation input commands that correspond to the trajectory: $\{d_i, t_i, \mathbf{J}_i\}$, respectively, where $i = 1, \dots, m$ reflects the number of demonstrations. The outputs of our training phase are

- The integral of the string of teleoperation input commands, $g_i = \int_0^{t_i} \mathbf{J}_i$
- The average teleoperation input command, $\bar{\mathbf{J}}_i \in \mathbf{J}_i$
- The position of the system at all times, $\mathbf{p}(t)$

The average command, in this case, provides information about the pilot's average in-flight velocity, and is obtained by taking the mean of all entries in \mathbf{J}_i . The integral, meanwhile, describes the area under the string of commands, as discussed in the previous section.

1) *Offline Training Data:* Our training data in this work consists of multiple demonstrations of a human-pilot flying forward at varying speeds for varying distances. In Fig. 6, we show the raw data received from the demonstrations. In this case, we have training samples where the pilot flies forward and then stops, which is why there are extended periods where there is no forward motion at the ends of the trajectories in Fig. 4.

Fig. 6. Training Set, Teleoperation Commands pictured left, Trajectories pictured right

With this data, we can train a model for trajectories that start and end with 0 speed. This training would only be effective if trajectories involved stopping intermittently throughout the trajectory. However, we desire a continuous movement between the discretized components of the trajectory. To satisfy this requirement, we segment the training data to include trajectories for demonstrations where the velocity does not start and end at 0. We are interested in three separate types of segments:

- Trajectory Start, where the segment begins with a velocity of 0 and ends with a certain nonzero velocity
- Trajectory Intermediate, where the segment begins and end with a certain nonzero velocity
- Trajectory End, where the segment begins with a certain nonzero velocity and ends with a velocity of 0

In order to expand our data for this purpose, we train on portions of the training set pictured in Fig. 6, which correspond to each of the three segments we outlined. The segments

are formed by cutting the training data and trajectories at the start, the middle, and the end. Shown in Fig. 7 are four sample from our training set of the velocities and trajectories that correspond to the intermediary segments. Training on not

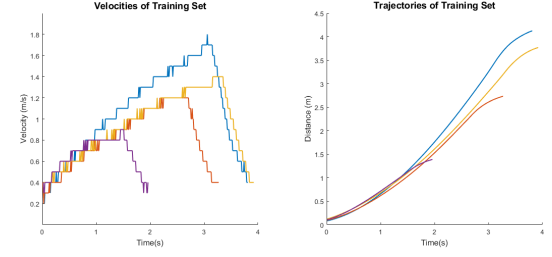

Fig. 7. Training Data with Trajectory Considerations

only trajectories that start and end with a velocity of 0, but also on segments enables more specific command generation based on where the system is in relation to the provided trajectory. For example, if the command for the middle of the trajectory (i.e., between two points that are neither the start nor end of the trajectory) needs to be generated, then the training from the trajectories in Fig. 7 is used.

2) *Thin-Plate Spline Regression Analysis:* The offline training data is applied to a thin-plate spline (TPS) surface regression to describe the relationship between training inputs and integral and average velocity. The general form of a thin-plate spline equation is

$$f(x, y) = a_1 + a_x x + a_y y + \sum_{i=1}^m w_i U(\|(x_i, y_i) - (x, y)\|) \quad (6)$$

where a_1, a_x , and a_y are scalar coefficients, w_i is a coefficient that corresponds to each specific trial, subject to the following smoothing condition:

$$\sum_{i=1}^m w_i = \sum_{i=1}^m w_i x_i = \sum_{i=1}^m w_i y_i = 0 \quad (7)$$

and the function U is of the form

$$U(r) = r^2 \log r \quad (8)$$

Given the corresponding z_i for each (x_i, y_i) pair, we solve the following linear system to obtain the coefficients w_i, \dots, w_m and a_1, a_x, a_y ,

$$\begin{bmatrix} K & P \\ P^T & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{w} \\ \mathbf{a} \end{bmatrix} = \begin{bmatrix} \mathbf{z} \\ \mathbf{o} \end{bmatrix} \quad (9)$$

where $K_{ij} = U(\|(x_i, y_i) - (x_j, y_j)\|)$, $P_i^* = (1, x_i, y_i)$, $\mathbf{0} \in \mathbb{R}^{3 \times 3}$ is a matrix of zeros, $\mathbf{o} \in \mathbb{R}^{3 \times 1}$ is a column vector of zeros, $\mathbf{w} \in \mathbb{R}^{m \times 1}$ and $\mathbf{z} \in \mathbb{R}^{m \times 1}$ are formed from w_i and z_i , respectively, and \mathbf{a} is the column vector with elements a_1, a_x, a_y .

Given the general framework for performing the thin-plate spline, we develop two separate relationships for our specific application. In our work, the first regression is applied to d (distance) and t (time) as inputs to obtain the integral of the commands $g_i = f(d_i, t_i)$ while the second one has the

same inputs to obtain the average teleoperation command $\bar{j}_i = h(d_i, t_i)$. With the functions we have obtained, we are able to find an estimated integral and steady-state command, g_u and \bar{j}_u , for any given desired distance and time, d_u and t_u , respectively,

$$g_u = f(d_u, t_u) \quad (10)$$

$$\bar{j}_u = h(d_u, t_u) \quad (11)$$

In Figs. 8 and 9, we show the surfaces that represent the two functions $g_i = f(d_i, t_i)$ and $\bar{j}_i = h(d_i, t_i)$, respectively. The points in these figures represent actual training data points, all of which lay on the surface created with the thin-plate spline.

Fig. 8. Integral vs Distance and Time

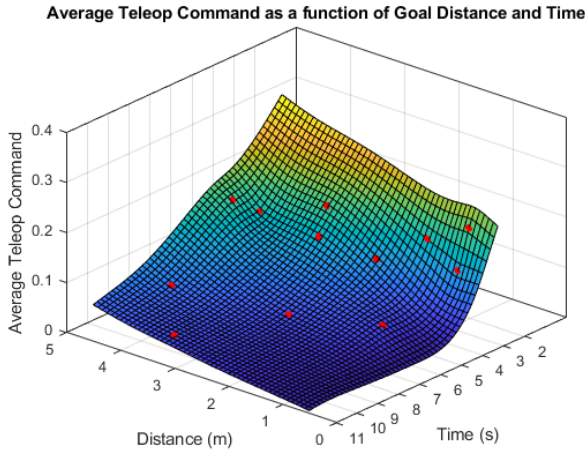

Fig. 9. Average Teleoperation Input Command vs Distance and Time

While a thin-plate spline is continuous, and a result can be obtained with any combination of distance and time as an input pair, the accuracy of the results of any pair (d_u, t_u) can suffer as the distance between evaluation points and training points increases [CITE]. In order to quantify this,

we leverage the standard error of the estimate, which is a statistic used to measure the accuracy of predictions given a certain type of regression [16] with known values:

$$\sigma_{est} \approx \frac{s}{\sqrt{m}} \quad (12)$$

where s is the sample standard deviation of all of the points in the training set and m is the number of training samples. The standard error, σ_{est} , is then used to determine the t-statistic for different test values. The t-statistic is defined as the ratio of departure of a test point from a known point to its standard error and is defined as

$$t_{\hat{\beta}} = \frac{|\hat{\beta} - \bar{\beta}|}{\sigma_{est}} \quad (13)$$

where $\hat{\beta}$ is the test point and $\bar{\beta}$ is the nearest known point. In equation (13), if $t_{\hat{\beta}} \geq 1$, that means that the test point $\hat{\beta}$ propagates an error higher than the standard error. Therefore, it is desirable to have $t_{\hat{\beta}} < 1$. Using a certain desired set-point for the t-statistic, t^* , the maximum allowable departure from known points is obtained:

$$\sigma_{est} t^* = |\hat{\beta} - \bar{\beta}| \quad (14)$$

This maximum departure, $\sigma_{est} t_{\hat{\beta}}$, is used to set the bounds for each training data point, for example:

$$\begin{aligned} \hat{\beta}_{\min} &= \bar{\beta} - \sigma_{est} t^* \\ \hat{\beta}_{\max} &= \bar{\beta} + \sigma_{est} t^* \end{aligned} \quad (15)$$

where β_{\min} and β_{\max} are the lower and upper bounds for known parameter β .

In our case, there are two inputs we are primarily concerned about for prediction; distance and time. As a result, we perform this calculation twice over, treating each of the two quantities as statistically independent, to obtain maximum departure values for each of the parameters: $\sigma_{d,est} t^*$ and $\sigma_{t,est} t^*$. In (10) and (11), the distance and time values are used together as input pairs, so a method to tie the two independent departure values together is desirable. Standard error rectangles [17], which create rectangular intervals around each data point, could be used for this purpose, but they are not necessarily accurate for smoothed surfaces, as rectangular regions would have non-differentiable corners, which are incongruous with smoothing conditions met by the TPS regression. An alternative method is to use standard error ellipses, which can be accurately attributed to smooth surfaces as per [17]. A general equation for a standard error ellipse for our maximum departure is shown below:

$$\left(\frac{x}{\sigma_{d,est} t^*} \right)^2 + \left(\frac{y}{\sigma_{t,est} t^*} \right)^2 = 1 \quad (16)$$

The ellipses at each point in our training data is calculated using the following parametrized equations:

$$\begin{aligned} x_i &= d_i + \sigma_{d,est} t^* \cos r \\ y_i &= t_i + \sigma_{t,est} t^* \sin r \end{aligned} \quad (17)$$

where r is the parameter in $[0, 2\pi]$, and $i = 1, \dots, m$ reflects each of the m training samples. Fig. 10(a), contains a pictorial representation of the standard error ellipses around each point. In Fig. 10(b), the surface shown in Fig. 8 is modified with a conforming boundary [18] created by the ellipses.

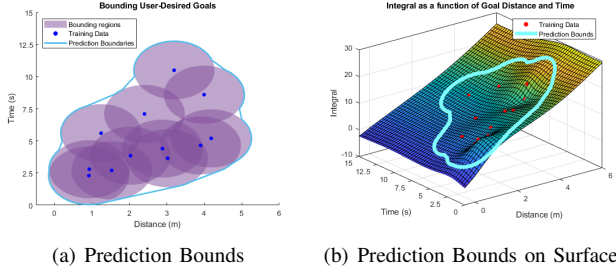

Fig. 10. Prediction Intervals and Bounds

Given these prediction bounds, we are able to assess whether or not our trajectory components will have accurate results in the command generation portion of this paper, which follows.

C. Autonomous Input Generation

In order for the system to autonomously reach a point within trajectory $\mathbf{p}_r(t)$, g_u and \bar{j}_u are obtained using equations (10) and (11), and the offline training samples are leveraged to generate a new string of commands. We first check back with our generated trajectory components to ensure that the distances of each segment are within the bounds of our error ellipses, as calculated in (17), and displayed in Fig. 10(a). If the error regions are violated, there is a possibility that the UAV will not reach the points in the desired trajectory, which is an indication of the strength and viability of the training set. After checking for possible error, commands are generated for each component of a trajectory, as described in Section V-A.

From the training set of m samples, we select the trial that has the closest integral, g_i , to the estimated integral g_u . This is done by forming an error vector, $\mathbf{e} \in \mathbb{R}^m$, where each element is defined by

$$e_i = |g_i - g_u|, \quad i = \{1, \dots, m\} \quad (18)$$

The lowest error is then found and is paired with the appropriate pre-trained sample, \mathbf{J}^* ,

$$\mathbf{J}^* = \mathbf{J}_i \in \mathbf{J} | e_i = \min(\mathbf{e}) \quad (19)$$

This optimal pre-trained sample is then adjusted to reflect the user-set time, t_u . This is done by performing vector interpolation to re-size \mathbf{J}^* , such that important features in the optimal command vector are not lost. These methods are often used for re-sizing complex images, and have shown effectiveness in minimizing feature loss [19]. Bicubic interpolation is our chosen method for re-sizing, as it performs better than nearest-neighbor and bilinear interpolation methods, while only marginally increasing computational

complexity [20]. The general form of a bicubic interpolation equation is

$$b(x) = \sum_{i=0}^3 a_i j^i \quad (20)$$

where j is an entry in vector \mathbf{J}^* and a represents the coefficients of the function at each point. Bicubic interpolation takes the weighted sum of the four nearest neighbors of each entry in the command vector in order to identify a function for the intermediate points between each value in \mathbf{J}^* . After resizing, we obtain the time adjusted input vector \mathbf{J}' .

The next step is to adjust the input vector such that the system reaches the user-set goal d_u . This is done by leveraging the average velocity information, that is, \bar{j}_u . Because distance is a function of average velocity and time, the scale time-adjusted vector \mathbf{J}' is scaled such that its mean is equivalent to \bar{j}_u . We then obtain

$$\mathbf{J}_a = \mathbf{J}' \left(\frac{\bar{j}_u}{\bar{j}'} \right) \quad (21)$$

In Fig. 11, we show visually the steps of command generation. In Fig. 11(a), we start with the original pre-trained command string that was shown above in Fig. 2. This flight travelled approximately 4.4 seconds for 3 meters. For testing purposes, our use input values are $d_u = 3.5\text{m}$ and $t_u = 3.75\text{s}$. As indicated, a time adjustment is made first; this is shown in Fig. 11(b). It is important to note that the average command, indicated by the dashed line, is still the same, which is a verification of feature retention aspect of bicubic interpolation from (20). If the vector were stretched without using an interpolation method, we would expect slight variation in the mean, which could damage the integrity of the final step, shown in Fig. 11(c), which is obtained using (21). At this point we have obtained the autonomous command string \mathbf{J}_a , which is then sent to the UAV to follow the trajectory $\mathbf{p}_r(t)$.

Fig. 11. Command Generation Process

D. Online Adaptation of Generated Commands

The commands generated in the previous section are generated and sent to the UAV in open-loop. While we have experimentally verified open-loop results for reasonable accuracy, we desire more assured trajectory tracking by closing the loop by controlling for any possible error. While executing generated command string, $\mathbf{x}_a(t)$, we monitor the error between the position of the vehicle, $\mathbf{p}(t)$ and the reference position as per the generated trajectory, $\mathbf{p}_r(t)$:

$$\xi(t) = \mathbf{p}(t) - \mathbf{p}_r(t) \quad (22)$$

The error $\xi(t)$ is attributed to the most recent command $\mathbf{J}_a(t)$, and a proportional controller is used to adjust the following command $\mathbf{J}_a(t+1)$ to obtain the closed-loop command $\mathbf{J}_c(t+1)$ as follows

$$\mathbf{J}_c(t+1) = \mathbf{J}_a(t+1) + k_p(t)\xi(t) \quad (23)$$

The proportional gain, $k_p(t)$, is automatically tuned based using a gradient descent method where the proportional gain is adjusted until the position error, $\xi(t)$ converges to 0. The initial value of our gain, k_p is set to 0, which indicates that we assume

$$k_p(t+1) = k_p(t) + \frac{\xi(t)}{\mathbf{p}_r(t)} \quad (24)$$

The quantity $\frac{\xi(t)}{\mathbf{p}_r(t)}$ relates the current error to the desired position within the trajectory.

VI. EXPERIMENTS

The proposed approach was validated experimentally using an Parrot Bebop 2 Drone quadrotor UAV, which arrives tuned and stable for teleoperation off-the-shelf. Since experiments were conducted indoors, a Vicon motion capture system was used to obtain the position and velocity of the vehicle. The teleoperation was performed using a node written in the ROS environment.

The training set was generating by having a human teleoperate the system 12 times with motion that only consisted of pitch commands. These training trajectories had different distances and took different amounts of time. We were also able to use this same training set to generate roll commands for our UAV. The regression and error analysis was done in Matlab to obtain the surfaces pictured in Section V-B, and are shown in Figs. 8, 9, and 10. Next, the command generation was done using the Image Processing Toolbox in Matlab. Lastly, the real experiments were conducted using ROS in conjunction with the Robotics System Toolbox to interface our regression models within the Matlab environment with ROS.

The first experiments consisted of tracking straight line distances and diagonal distance, to validate that x and y components as discussed in Section V-A can be attained accurately. For straight line distances, we use a trajectory that travelled 1.85m in 5 seconds.

To validate the x and y component, we use a diagonal distance where the UAV travels -1.7m in the x -direction and 2.3m in the y direction.

To further validate the approach, a square-shaped trajectory, and a discretized 8 shaped trajectory were tested.

VII. CONCLUSIONS

In this work, we have presented an approach that enables autonomous flight on off-the-shelf quadrotors that are primarily tuned for teleoperation. Our approach shows that we can use a small training set along with a regression analysis

to generate commands for any trajectory, along with adapting and closing the loop in real-time to reduce tracking error. For future work, we plan to increase
